- **Inherited disorder/disease:** genetic disorder not related to breed standard.

## **1. Abstract**

In first opinion veterinary practice differential diagnoses play an important role in the diagnostic process. Many differential diagnoses exist for the different animal species and breeds treated by a veterinarian. In dogs, a special situation might be of importance. Influenced by the manners of (in)breeding, mainly based on selection of breed characteristics, inheritable disorders might appear in a much higher frequency in pedigree dogs compared to crossbreeds. In this study general differential diagnoses per organ system are set up based on the VeNom Codes, literature search and interviews with specialists of the University Clinic for Companion animals (UKG). These general lists of differential diagnoses per organ system are compared to data collected from databases of first and secondary care clinics for the Chihuahua, Labrador, French Bulldog and crossbreeds. Analysis of these data shows that breed is influential on the differential diagnosis and the diagnostic process in first opinion practice.

## **2. Introduction**

In the Netherlands over 2.800 veterinarians are employed in companion animal practice, working in at least 1.000 practices all over the country ([KNMvD](#)). The majority of these practices are first line practices, where primary care is offered to the broad scala of animal species kept as companion animal. In first line practice, specialized equipment is often limited and complex patients can be referred to specialized, secondary care clinics.

Aforesaid first opinion veterinarians experience busy days, where an average of 20 patients a day is not uncommon. Patients with a variety of problems visit the practice, for which the veterinarian has to try and find a solution within 10-20 minutes. The combination of extent of the range of patients, the time constraints and financial limitations often make it impossible for a first opinion veterinarian to do all the diagnostic testing he/she would like to perform, to confirm the diagnosis. Therefore, working with a list of differential diagnosis is general practice and a useful tool.

The veterinarian performs the anamnesis and clinical research to determine which problems the patient has and which organ system is affected. Based on the results, a differential diagnosis is considered, containing a list of possible diagnoses for the patient at hand. Using the information given by the owner combined with the patients' symptoms, prioritizing can take place within the list. However, frequently a number of diagnoses remain highly likely. An additional support for the choice of further investigation and the decision to which therapy will be applied, is prioritizing based on the incidence of a disorder. Common disorders are ranked higher on the list of differential diagnoses than rare ones. However, exact numbers concerning the frequency of incidents most likely are non-existent, bringing the veterinarian to a diagnosis mainly based on his personal experience.

Separate lists of differential diagnoses exist for dog and cat, because these animals show different disorders and the incidence of similar disorders differ per animal species. For example, elbow dysplasia is often seen in dogs ([Kirberger et al, 1998](#)), whilst this disorder is very rare in cats. Besides, it is known that the dog is the most diverse animal species in the world, over 400 breeds are known, variable from 0.5-95 kg ([Arman, 2007](#)). In purebred dogs more than 500 inherited diseases exist, some of which are only described in a few, or even a single, breeds ([Arman, 2007](#)). Keeping this in mind, the hypothesis is set up that in pedigree dogs breed influences the differential diagnosis and the diagnostic proces in first opinion practice.

Historically dogs were used as an utility animal, for example as a watchdog or for herding of cattle. Today, dogs are still used as guard or herding dogs, but the vast majority are a companion animals. The latter must meet various requirements of humans, in character and appearance. The pursuit of an ideal

appearance has had much influence on the high frequency of inheritable breed related disorders that can be found in many pedigree dogs. The first dog shows were held in the 19th century and specific breeds and breed standards were established. In order to comply with these standards and create breed purity, specific breeding practices were used, such as the overuse of popular sires and/or mating between related dogs. Besides, the number of individuals used as founding stock, which is small in many breeds, and how closely related they are, has an influence on the genetic health of a breed (Leroy et al, 2011).

These breeding practices have led to inheritable breed-related disorders, such as conformation related disorders, a direct consequence of breed standards, and inherited diseases. One of the reasons for the abnormally high occurrence of inherited diseases, is genotypic homozygosity. Heterozygosity is an important occurrence for species' survival and fortitude, but many desired breed traits are recessive and require that both copies of the inherited allele be the same for the trait to be expressed phenotypically (Arman, 2007). When breeders select for desired traits, they also select for other genes that are specifically linked to these 'good genes'. When alleles do not assort independently, the doubling up of both good and bad genes occurs. So, when breeders select for preferred traits, they may also select for deleterious genes that can result in diseases. All individuals carry deleterious genes, but because these deleterious genes are ordinarily recessive and usually inherited in a heterozygous way, there is no harmful impact on health (Arman, 2007). The resultant purebreds possess homozygous genes for the existence of over 500 inherited diseases (Arman, 2007).

Besides these genetic defects, which can result in inherited diseases, the desired trait is often harmful in itself. If such a conformational trait causes health problems, it is called a conformation related disorder. Since these features are set in the breed standard, this can be considered a conscious choice of breeders and consumers. An example of a harmful breed characteristic is the brachycephalic obstructive syndrome, seen in, amongst others, the French Bulldog. Since having a short brachycephalic skull is an important characteristic of the breed, the proportions of the upper respiratory system have changed and many animals of this breed suffer from breathing problems (Arman, 2007; Asher et al, 2009).

An increasing number of studies have been conducted about inheritable breed related disorders (Ubbink et al., 2000; Mäki et al., 2001; Urfer, 2009; Wellmann and Pfeiffer, 2009; van der Beek et al., 1999; Lewis et al., 2010). However, the incidence and impact of diseases in pedigree breed's populations in the Netherlands are unknown. Therefore the "The Expertise Centre Genetics for Companion Animals of Utrecht University" has started a wide scaled investigation called "*Incidental breed related inheritable disorders and harmful breed characteristics in Dutch populations of small animals*". This project aims to establish the incidence of breed standard related disorders and inheritable diseases in populations of pedigree dogs and cats, by implementing a national veterinary disease monitoring database, which will help policy makers to develop health programs for Dutch pedigree breeds. The results of this pilot study will be

*The influence of breed standard related disorders and inheritable diseases in pedigree dogs on differential diagnoses and the diagnostic process.*

the basis for this research, in which the hypothesis was tested that breed standard related disorders and inherited diseases in a pedigree population will influence the priority in differential diagnosis and the diagnostic process.

### **3. Materials and methods**

#### *3.1 Differential diagnoses per organsystem*

In order to assess the influence of breed standard related disorders and inheritable diseases in pedigree dogs on priority in the differential diagnoses per breed and the diagnostic process, randomly organized differential diagnoses were compared to differential diagnoses per breed in the selected organs. To start with, randomly organized differential diagnoses were set up - in a stepwise approach. First, organs were classified according to anatomy, mainly based on the ATCvet system ([www.whocc.no/atcvet](http://www.whocc.no/atcvet)), as well with reference to published literature (Nelson et al, 2009; Ettinger et al, 2009). Second, non-infectious diseases documented by the VeNomCoding Group were assigned to the organs. The VeNomCoding Group has developed a standard set of clinical veterinary terms (VeNom Codes), for use in first opinion veterinary practice management systems and referral veterinary hospital electronic patient records ([www.venomcoding.org](http://www.venomcoding.org)). Third, an additional literature search was performed. A wide variety of scientific literature was used, the most important source being veterinary textbooks (Nelson et al, 2009; Ettinger et al, 2009). All disorders named in the VenomCodes and veterinary textbooks per organ system, were listed. Using this comprehensive list of disorders, a systematic search of scientific and veterinary literature was conducted, to check the importance for first opinion veterinary practice, and/or the incidence in the country where this research was carried out (The Netherlands). Online bibliographic databases were used, such as PubMed and Google Scholar, employing each of the following search criteria:

[Disease name] AND [DOG OR CANINE]

[Disease name] AND [DOG OR CANINE] AND [HOLLAND OR NETHERLANDS]

Each organ system was linked to a certain discipline of the UKG, where board certified specialists per discipline were requested to verify the lists.

By these four steps, accessible lists of general differential diagnoses were generated, containing all non-infectious disorders important in first opinion practice.

#### *3.2 Pilot study first line practice*

A pilot study has been performed to measure incidences of breed related disorders in four breeds – Chihuahua, French Bulldog, Labrador Retriever and Persian cat (Meijndert, 2014). The cumulative incidence of disease in selected organs was calculated from manually collected data of ten first line veterinary clinics. The organ systems were selected by literature search per breed, interviews with board certified specialists on relevance of diseases for the Dutch populations and database analysis at the UKG. The obtained incidences in the

first line veterinary clinics, were compared to incidences in a control group of crossbreed dogs or regular housecats, selected similarly from the ten practices.

Per breed the organ systems in which disease frequency was significantly higher than the control group were selected. These organ systems have been used in this study for the comparison of differential diagnosis.

### *3.3 UKG database analysis*

The results of the pilot study ([Meijndert, 2014](#)) revealed in which organs disease frequency was higher in Chihuahua, French Bulldog, Labrador Retriever compared to the control group of crossbreeds. A database analysis at the UKG was carried out to indicate the breed specific disorders in the selected organs. To perform this analysis, the selected organ systems were matched to the corresponding disciplines within the UKG. Several parameters were investigated per breed, such as:

- Total number of Chihuahua, French Bulldog, Labrador Retriever and crossbreed consultations at the UKG per selected discipline
- Per selected discipline: which disorders were diagnosed in Chihuahua, French Bulldog, Labrador Retriever and crossbreeds

The following parameters were investigated for each individual dog:

- Patient number
- Consult date
- Breed
- Date of birth
- Consulted discipline
- Diagnosis

In order to include a sample size large enough for statistical evidence, data collected over a time span of five years were analyzed. The period 2009-2013 was used, since this is the most current information available. The crossbreed consultations formed the control group in this study, containing all dogs signed up with 'no breed' or 'crossbreed'. Dogs joining a screening program of a Kennel Club or breed association, were excluded from this analysis.

For each breed the three most diagnosed diseases per selected discipline were used for the statistical analysis.

### *3.4 Statistical analysis*

Per breed the three most diagnosed diseases per discipline were used for the statistical analysis. A Fisher's Exact test was used to evaluate the significant difference ( $P<0,05$ ) between the number of pedigree dogs (Chihuahua, French Bulldog and Labrador Retriever) and the number of crossbreeds, diagnosed a certain disease per discipline at the UKG. When significant differences were detected, the mean age of occurrence was calculated for disease in pedigree dogs and crossbreeds, together with the median, minimum and maximum age of occurrence. A median test was computed to test the statistical difference in median age of occurrence. All results were compiled and analyzed with SPSS version 20.

### *3.5 New ranking*

If a statistically significant difference was evaluated, the disease is proved to occur more often in the selected breed compared to crossbreeds. This difference in incidence influences the differential diagnosis, statistically significant over-represented diseases are more likely to occur and thus placed higher in ranking.

## 4. Results

### 4.1 Differential diagnoses per organ system

The classification of organs (based on the ATCvet system) is shown in figure 1.

Fig. 1: Organ classification (<http://www.whocc.no/atcvet>)

<b>Organ classification</b>	
<b>Alimentary tract</b>	Mouth and throat Gastrointestinal tract Liver, biliary system and vena porta Exocrine pancreas
<b>Blood and blood forming organs</b>	
<b>Cardiovascular system</b>	
<b>Dermatological disorders</b>	
<b>Urogenital system</b>	Reproductive organs and mammary glands Kidneys Bladder and Urinary tract
<b>Systemic hormonal changes (excl. sex hormones and insulin)</b>	Pituitary, hypothalamus and adrenals Parathyroid gland Thyroid gland Endocrine pancreas
<b>Neoplastic disorders</b>	
<b>Musculo-skeletal system</b>	Hip joint Elbow joint Stifle joint Remaining joints Vertebral column
<b>Nervous system</b>	Brain Spinal cord – cervical Spinal cord – thoracolumbal Spinal cord – lumbosacral Peripheral nerves
<b>Respiratory system</b>	Upper airway Lower respiratory tract
<b>Eyes</b>	
<b>Ears</b>	

Differential diagnoses of organs of importance are shown in fig. 2 (Musculo-skeletal system), fig. 3 (Reproductive organs and mammary glands), fig. 4 (Eyes), fig. 5 (Ears), fig. 6 (Respiratory system) and fig. 7 (Vertebral column). The differential diagnoses of the remaining organs shown in fig. 1, are attached in Annex 1.

Fig. 2: Differential diagnosis Musculo-skeletal system

### **Musculo-skeletal system**

#### **Hip joint**

- Hip dysplasia
- Avascular necrosis head of femur (Calvé-Legg-Perthes)
- Osteoarthritis/-arthritis
- Hip luxation
- Fracture
- Neoplasm

#### **Elbow joint**

- Elbow dysplasia
  - Ununited anconeal process (UAP)
  - Fragmented coronoid process (FCP)
  - Osteochondrosis dissecans (OCD)
  - Elbow incongruity (EI)
  - Medial compartment syndrome (MCD)
- Osteoarthritis/-arthritis

#### *4.2 Results pilot study*

The organsystems, in which disease frequency was significantly higher than the control group, included for the Chihuahua the musculo-skeletal system and reproduction, for the French Bulldog the eyes and ears, respiratory system, vertebral column and reproduction and for the Labrador Retriever the musculo-skeletal system (Meijndert, 2014) (table 1). The organ systems, used for the differential diagnoses, are linked to UKG disciplines. The matches are shown in table 1.

Table 1: organsystems and UKG-disciplines per breed

Breed	Organsystem	UKG discipline
Chihuahua	- Musculo-skeletal system - Reproductive organs and mammary glands	- Orthopedics - Reproduction
French Bulldog	- Eyes - Ears - Respiratory system – upper airway - Vertebral column - Reproductive organs and mammary glands	- Ophthalmology - KNO - Ears - KNO - Upper airway - Orthopedics/ Neurology - Reproduction
Labrador Retriever	- Musculo-skeletal system	- Orthopedics

#### *4.3 Results statistical analysis & new ranking*

The total number of Chihuahua, French Bulldog, Labrador Retriever and crossbreed consultations at the UKG per selected discipline is shown in table 2. These numbers contain the consultations with a diagnosis documented, the actual numbers of consultations were much higher (written in brackets). The consultations with no diagnosis documented, were not taken into consideration in the statistical analysis. For the disciplines Ears, Upper airway and Vertebral column, no actual number of consults per subdiscipline was calculated, represented with (?) in table 2.

*The influence of breed standard related disorders and inheritable diseases in pedigree dogs on differential diagnoses and the diagnostic process.*

Table 2: UKG-consultations per breed per discipline

Discipline	Chihuahua	French Bulldog	Labrador Retriever	Crossbreeds
Reproduction	1 (6)	2 (4)	n.a.	14 (35)
Orthopaedics	22 (38)	n.a.	137 (254)	136 (216)
Ophthalmology	n.a.	57 (70)	n.a.	180 (231)
KNO - Ears - Upper airway	n.a.	32 (46) 11 (?) 21 (?)	n.a.	50 (80) 22 (?) 38 (?)
Vertebral column - Orthopaedics - Neurology	n.a.	27 (?) 15 (?) 12 (?)	n.a.	31 (?) 20 (?) 11 (?)

n.a. = non applicable

### Chihuahua

UKG database analysis of the discipline Reproduction resulted in too little information to perform statistical analysis, hence this discipline is left out of consideration. The results of the statistical analysis of the three most diagnosed diseases in the discipline Orthopaedics, are shown in table 2. Statistically significant values are marked with \*, if  $P<0.05$ .

Table 3: Chihuahua, results statistical analysis Orthopaedics

Orthopaedics	Chihuahua	Crossbreed	p-value (FE)
Patellar luxation	11	13	0,000*
Fracture	3	16	0,713
CCL (cranial cruciate ligament) injury	2	27	0,372
Total	22	136	

As shown in table 2, patellar luxation was statistically significant more diagnosed in Chihuahuas compared to crossbreeds. All cases in the Chihuahua were medially luxating patellas. The median age of occurrence in Chihuahuas 1,1 year, whilst for crossbreeds 2,6 year. This difference in median age of occurrence is not

statistically significant.

The fact that patellar luxation occurs statistically significant more often in Chihuahuas compared to crossbreeds, results in a higher ranking of patellar luxation in differential diagnosis for this breed. Chihuahuas with musculo-skeletal problems, will have a higher chance of suffering from patellar luxation and thus suffering from a stifle joint problem compared to other musculo-skeletal disorders. Stifle – and patellar luxation, are placed higher in ranking compared to the general differential diagnosis of musculo-skeletal system (fig. 7). The disorder concerned is highlighted in grey.

**French Bulldog**

In the French Bulldog, UKG database analysis was performed for the disciplines Ophthalmology, KNO (ears, upper airway), Orthopaedics/Neurology (vertebral column) and Reproduction. The same as for Chihuahuas, not enough samples were documented to be able to statistically test the discipline Reproduction. For the other disciplines, the three most diagnosed disorders and the results of the statistical test are shown in table 3.1- table 3.3. Statistically significant values are marked with \*, if  $P < 0.05$ .

*The influence of breed standard related disorders and inheritable diseases in pedigree dogs on differential diagnoses and the diagnostic process.*

Table 4.1: French Bulldog, Results statistical analysis Ophthalmology

Ophthalmology	French Bulldog	Crossbreed	p-value (FE)
Cataract	11	51	0,161
Ulcus	9	10	0,043*
Glaucoma	4	12	1,000
Total	57	180	

Table 4.2: French Bulldog, Results statistical analysis KNO, ears

Ears	French Bulldog	Crossbreed	p-value (FE)
Otitis externa	9	18	1,000
Otitis media et interna	2	2	0,572
Miscellaneous	0	2	n.a.
Totaal	11	22	

Table 4.3: French Bulldog, Results statistical analysis KNO, upper airway

Upper airway	French Bulldog	Crossbreed	p-value (FE)
BOS (brachycephalic obstructive syndrome)	17	4	0,000*
Miscellaneous°	4	32	n.a.
Total	21	38	

° four different diseases, all diagnosed once in the French Bulldog.

Table 4.4: French Bulldog, Results statistical analysis Orthopaedics/Neurology (Vertebral column)

Vertebral column	French Bulldog	Crossbreed	p-value (FE)
Hernia	26	20	0,003*

Degenerative lumbosacral stenosis	1	6	0,108
Miscellaneous	0	5	n.a.
Total	27	31	

In Ophthalmology the diagnosis ulcus was statistically significant, however, in the discipline Ears, no statistically significant diseases were found. In the differential diagnosis for the organ system linked to the discipline Ears, the priority of diseases did not change. The median age of occurrence of French Bulldogs suffering from ulcus, was statistically significant younger than the median age of occurrence in crossbreeds.

In Upper airway and Vertebral column, respectively BOS and hernia were assessed statistically significant. The median age of occurrence for French Bulldogs with BOS 1,8 years, whilst for crossbreeds 4,0 years, which is not statistically significant. French Bulldogs suffered from hernia, at a statistically significant younger median age compared to crossbreeds (respectively 3,1 years and 6,5 years).

The statistically significant findings change the differential diagnosis of the Upper airway, Eyes and Vertebral column. The breed-specific differential diagnoses for the French Bulldog are shown right in fig. 8 (Upper airway), fig 9 (Eyes) and fig. 10 (Vertebral column), left the general differential diagnoses are shown. The disorders concerned are highlighted in grey.

#### Labrador Retriever

The only discipline statistically relevant for the Labrador Retriever was Orthopaedics, with elbow dysplasia, CCL (cranial cruciate ligament) injury and neoplasia as most diagnosed diseases. The results of the statistical analysis are shown in table 4, statistically significant values are marked with \*, if  $P<0.05$ .

Table 5: Labrador Retriever, Results statistical analysis Orthopaedics

<b>Orthopaedics</b>	<b>Labrador Retriever</b>	<b>Crossbreed</b>	<b>p-value (FE)</b>
Elbow dysplasia	48	18	0,000*
CCL (cranial cruciate ligament) injury	26	27	0,879
Neoplasia	10	11	0,825
Total	137	136	

Elbow dysplasia occurred statistically significant more often in Labrador Retrievers compared to crossbreeds. This finding changes the differential diagnosis of musculo-skeletal system for the Labrador Retriever, compared to the general differential diagnosis. Both differential diagnoses are shown in fig. 11 , to provide an accessible overview of the breed-related changes.

## 5. Discussion

This study has assessed the influence of breed related disorders on differential diagnoses and the diagnostic process of a veterinarian. For the Chihuahua, French Bulldog and Labrador Retriever specific differential diagnoses were conducted, based on the incidence of certain disorders per breed. These new differential diagnoses, were compared to randomly set up differential diagnoses of the same organ systems. By statistically demonstrating that these differential diagnoses differ, the hypothesis is proved that breed certainly is of influence.

Although the tested hypothesis is proven correct, we could possibly have found more inherited diseases in the UKG database, if more data was available. In as little as 50% of all patients records, a diagnosis was documented. If no diagnosis was documented, these patients were not taken into consideration. Hereby, the number of data was often too little for hard statistically significant evidence and only the obvious cases came apparent. With hard statistically significant evidence, it would be possible to even remove disorders from the differential diagnosis in some breeds. For this purpose, more data is needed.

Data for this purpose could be collected by manually checking the patients records and extracting the non-documented diagnoses from other fields in the records. A threat of this system, is misinterpretation by researchers and thus drawing conclusions to false diagnoses. Besides, this manual operation is extremely time-consuming. In pursuit of collecting more, solid, data from the UKG database in the future, a standardized way of documentation is recommended. If documentation at the UKG will be carried out carefully and in such a standardised way, an extremely valuable source will be created. The system of differential diagnoses ordered per organ system/anatomical sub-location we have developed and used here, based on international standard nomenclature, would be directly applicable and suitable for the UKG patient documentation system.

However, besides this non-foreseen disadvantage of using the UKG database as a source, one should be aware of certain limitations when using the database of a secondary care clinic. It is widely recognized that the clinical spectrum of diseases may be distorted in secondary care clinics, due to the selective referral of more severe or complicated cases. This phenomenon is called "referral bias" (Nelson et al, 1987). This referral bias was circumvented by first studying the situation in first line practices, which represent the current companion animal population in the Netherlands. Based on the results in first line practice, further investigation was performed at the UKG. Combining first and secondary care databases in research, a reliable source of information is created for this research.

Consequently, all in first line practice selected organ systems, were expected to show statistically significant disorders in the selected breeds. However, this did not point out to be correct for all selected organ systems. For example, the difference in occurrence of the most diagnosed ear disease in French Bulldogs,

otitis externa, was not statistically significant compared to crossbreeds. The most likely explanation is that the UKG database contains only diseases which are more or less frequently referred by first line practice. A disease like otitis externa will usually be easily diagnosed and treated in first line practice and therefore not be represented in the UKG database.

Another remarkable finding in this study, is the extremely few Chihuahuas, French Bulldogs and crossbreeds consulting the discipline Reproduction. A possible reason could be a lack of documentation, which is unlikely because all patients visiting the UKG must have a patient record (with or without diagnosis) in order to pay for their consult. An alternative reason for the low number of patients in this discipline, is that the diseases pointed out as important ([Meijndert, 2013](#)), are solved in first line practice. This makes sense, as dystocia, the most important problem seen in first line practice, is treated with a first line operation – a caesarian. Consequently, these patients do not consult secondary care clinics and are not recorded in the UKG database. The aforesaid “referral bias” interferes with the results of this study.

Apart from the few disciplines not showing disorders significantly over-represented in certain breeds, the majority of studied disciplines did. The priority in four differential diagnoses has changed based on breed, which can be useful for the veterinarian with a Chihuahua, French Bulldog or Labrador Retriever in his/her consulting room. A dog with a musculo-skeletal problem, being a Chihuahua, is at higher risk of patellar luxation than a crossbreed dog. Thus, the differential diagnosis for a lame Chihuahua, differs from the differential diagnosis of a lame crossbreed dog. The results of this study simplify the prioritising in differential diagnoses, since statistically significant breed-related differences can support the veterinarians’ experience. Although medical history and careful clinical examination remains extremely important, by simplifying the prioritising in differential diagnoses, the choice for additional research, or even treatment, is facilitated. This study revealed only four differential diagnoses to be changed by breed, one can imagine that with more, carefully documented data and more research, breed-specific differential diagnoses per organ system can be conducted, positively contributing to first line veterinary practice.

## **6. Conclusion**

This study identified that breed standard related disorders and inherited diseases in a pedigree population influence the priority in differential diagnosis and the diagnostic process. By combining first en secondary care databases in this research, the differential diagnoses for several organ systems differed between pedigree dogs and crossbreeds. These findings facilitate prioritising in differential diagnoses of consulting purebred dogs, positively influencing the diagnostic process.

## **7. Acknowledgements**

Ondanks dat dit hele verslag in het Engels is, ga ik het dankwoord lekker in het Nederlands typen. Allereerst wil ik Jan Rothuizen bedanken voor zijn prettige en professionele begeleiding tijdens deze onderzoeksstage. Voornamelijk in het controleren en verbeteren van de ddx-lijsten heeft u een grote rol gehad en ik vond onze meetings altijd zeer prettig en efficient.

Daarnaast wil ik graag de specialsiten van de UKG bedanken voor hun tijd en moeite om hun kundige blik over de ddx-lijsten te laten gaan en mij te voorzien van de nodige feedback.

Tot slot wil ik, uiteraard, Liesbeth Meijndert bedanken. Dankzij jou heb ik de kans gekregen om deze onderzoeksstage te doen en ook nog op zo'n korte termijn, bedankt dat je mij deze kans hebt gegeven! In no time was het geregeld en kon ik aan de slag. De rest van mijn onderzoekstage bleef je super betrokken en voor alles kon ik bij je terecht, op elk moment van de dag. Zelfs je vriendje heb je ingeschakeld toen ik vast liep met SPSS, omdat jij op dat moment even geen computer met SPSS bij de hand had, echt super! Telkens weer was je bereid om mijn verslag na te kijken en gaf je hele nuttige feedback. Na 292 mailtjes over en weer (tel maar na!), wordt het wel een beetje afkicken.. Liesbeth, super bedankt voor al je hulp!
